Abstract

Recent advances in domain adaptation allow us to construct networks that are invariant to certain labeled factors. The reverse gradient algorithm uses an adversarial learning approach to train a network to produce the desired label as well as to deceive a second classifier that is trained on adaptation labels. This is tightly connected to the ideas behind generative adversarial networks (GANs). Therefore, some insights for training GANs are needed for the reverse gradient’s successful application. We adapt this approach to train an acoustic system that is invariant to undesirable factors such as the recording environment noise type. We also investigate speaker identity invariance and conduct experiments on two popular datasets.

Index Terms: speech recognition, adversarial training, reverse gradient

1. Introduction

One of the most challenging aspects of automatic speech recognition (ASR) is the mismatch between the training and testing acoustic conditions. During testing, a system may encounter new recording conditions, microphone types, speakers, accents and types of background noises. Furthermore, even if the test scenarios are seen during training, there can be significant variability in their statistics. Thus, it’s important to develop ASR systems that are invariant to unseen acoustic conditions.

Several model and feature based adaptation methods such as Maximum Likelihood Linear Regression (MLLR), feature-based MLLR and iVectors (Saon et al., 2013) have been proposed to handle speaker variability; and Noise Adaptive Training (NAT; Kalinli et al., 2010) and Vector Taylor Series (VTS; Un et al., 1998) to handle environment variability. With the increasing success of Deep Neural Network (DNN) acoustic models for ASR (Hinton et al., 2012; Seide et al., 2011; Sainath et al., 2011), end-to-end systems are being proposed (Miao et al., 2015; Sainath et al., 2015) for modeling the acoustic conditions within a single network. This allows us to take advantage of the network’s ability to learn highly non-linear feature transformations, with greater flexibility in constructing training objective functions that promote learning of noise invariant representations. The main idea of this work is to force the acoustic model to learn a representation which is invariant to noise conditions, instead of explicitly using noise robust acoustic features (Section 3). This type of noise-invariant training requires noise-condition labels during training only. It is related to the idea of generative adversarial networks (GAN) and the gradient reverse method proposed in Goodfellow et al. (2014) and Ganin and Lempitsky (2014) respectively (Section 2). We present results on the Aurora-4 speech recognition task in Section 4 and summarize our findings in Section 5.

2. Related Work

Generative Adversarial Networks consist of two networks: the generator and the discriminator. The generator network G has an input of randomly-generated feature vectors and is asked to produce a sample, e.g. an image, similar to the images in the training set. The discriminator network D can either receive a generated image from the generator G or an image from the training set. Its task is to distinguish between the “fake” generated image and the “real” image taken from the dataset. Thus, the discriminator is just a classifier network with a sigmoid output layer and can be trained with gradient backpropagation. This gradient can be propagated further to the generator network (assuming that the output of the generator is continuous).

The two networks in the GAN setup are competing with each other: the generator is trying to deceive the discriminator network, while the discriminator tries to do its best to recognize if there was a deception, similar to adversarial game-theoretic settings. Formally, the objective function of GAN training is

$$\min_G \max_D V(D, G) = \mathbb{E}_{\mathbf{x} \sim p_{\text{data}}(\mathbf{x})} [\log D(\mathbf{x})] + \mathbb{E}_{\mathbf{z} \sim p_{\mathbf{z}}(\mathbf{z})} [\log(1 - D(G(\mathbf{z})))].$$

The maximization over the discriminator D forms a usual cross-entropy objective, the gradients are computed with respect to the parameters of D . The parameters of G are minimizing the classification objective using the gradients propagated through the second term. The minimization over G makes it produce samples which D classifies as originating from the train data. Several practical guidelines were proposed for optimizing GANs in Radford et al. (2015) and further explored in Salimans et al. (2016).

Prior work by Ganin and Lempitsky (2014) proposed a method for training a network which can be adapted to new domains. The training data consists of the images labeled with classes of interest and separate domain (image background) labels. The network has a Y-like structure: the image is fed to the first network which produces a hidden representation h . Then this representation h is input to two separate networks: a domain classifier network (D) and a target classifier network (R). The goal of training is to learn a hidden representation that is invariant to the domain labels and still performs well on the target classification task, so that the domain information doesn’t interfere with the target classifier at test time. Similar to the GAN objective, which forces the generation distribution be close to the data distribution, the *gradient reverse method* makes domain specific distributions similar to each other.

The network is trained with three goals: the hidden representation h should be helpful for the target classifier, harmful for the domain classifier, and the domain classifier should have a

Figure 1: The model consists of three neural networks. The encoder E produces the intermediate representation h which is used in the recognizer R and in the domain discriminator D . The hidden representation h is trained to improve the recognition and minimize the domain discriminator accuracy. The domain discriminator is a classifier trained to maximize its accuracy on the noise type classification task.

good classification accuracy. More formally, the authors define the loss function as

$$L = L_1(\hat{y}, y; \theta_R, \theta_E) + \alpha L_2(\hat{d}, d; \theta_D) - \beta L_3(\hat{d}, d; \theta_E), \quad (1)$$

where y is the ground truth class, d is the domain label, corresponding hat variables are the network predictions, and θ_E, θ_R and θ_D are the subsets of parameters for the encoder, recognizer and the domain classifier networks respectively. The hyper-parameters α and β denote the relative influence of the loss functions terms.

The effectiveness of representations produced by a neural network for internal noise reduction is discussed in Yu et al. (2013) and this work sets a baseline for experiments on the Aurora-4 dataset. Recently, in Shinohara (2016) a multilayer sigmoidal network was trained in an adversarial fashion on an in-house transcription task corrupted by noise. [t]

3. Invariant Representations for Speech Recognition

Most ASR systems are DNN-HMM hybrid systems. The context dependent (CD) HMM states (acoustic model) are the class labels of interest. The recording conditions, speaker identity, or gender represent the domains in GANs. The task is to make the hidden layer representations of the HMM state classifier network invariant with respect to these domains. We hypothesize that this adversarial method of training helps the HMM state classifier to generalize better to unseen domain conditions and requires only a small additional amount of supervision, i.e., the domain labels.

Figure 1 depicts the model, which is same as the model for the gradient reverse method. It is a feed-forward neural network trained to predict the CD-HMM state, with a branch that predicts the domain (noise condition). This branch is discarded in the testing phase. In our experiments we used the noise condition as the domain label, merging all noise types into one label and defining ‘clean’ as the other label. Our training loss function is Eq. 1 with L_3 set to $d \log(1 - \hat{d}) + (1 - d) \log(\hat{d})$ for stability during training. L_3 term maximizes the probability of an incorrect domain classification in contrast to the gradient reverse where the correct classification is minimized. The terms L_1 and L_2 are regular cross-entropies which are minimized with

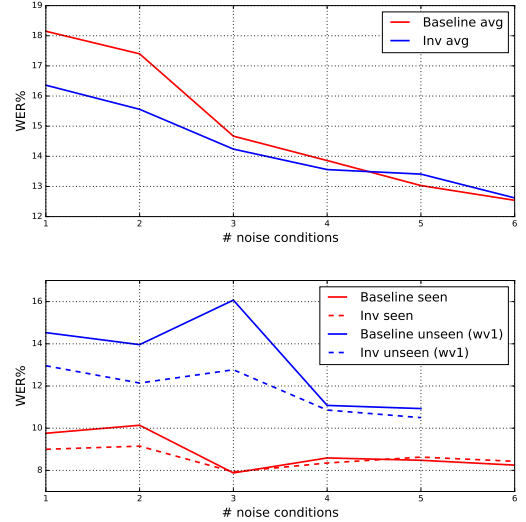

Figure 2: Top: Average performance of the baseline multi-condition and invariance model varying with the number of noise conditions used for training. Bottom: Average performance on seen versus unseen noise conditions. Testing was performed on all wv1 conditions (Sennheiser microphone).

corresponding parameters θ_E and θ_D . For simplicity, we use only a single hyper-parameter – the weight of the third term.

4. Experiments

We experimentally evaluated our approach on the well-benchmarked Aurora-4 (Parihar and Picone, 2002) noisy speech recognition task. Aurora-4 is based on the Wall Street Journal corpus (WSJ0). It contains noises of six categories which were added to the clean data. Every clean and noisy utterance has been filtered to simulate the frequency characteristics. The training data contains 4400 clean utterances and 446 utterances for each noise condition, i.e., a total of 2676 noisy utterances. The test set consists of clean data, data corrupted by 6 noise types, and data recorded with a different microphone for both the clean and noisy conditions.

For both the clean and noisy data, we extracted 40-dimensional Mel-filterbank features with their deltas and delta-deltas spliced over ± 5 frames, resulting in 1320 input features that were subsequently mean and variance normalized. The baseline acoustic model was a 6-layer DNN with 2048 rectified linear units at every layer. It was trained using momentum-accelerated stochastic gradient descent for 15 epochs with new-bob annealing (as in Morgan and Bourlard, 1995; Sainath et al., 2011).

To evaluate the impact of our method on generalization to unseen noises, we performed 6 experiments with different sets of noises seen during training. The networks were trained on clean data, with each noise condition added one-by-one in the following order: airport, babble, car, restaurant, street, and train. The last training group included all noises and therefore matched the standard multi-condition training setup. For every training group, we trained the baseline and the invariance model, where we branched out at the 4th layer to a binary classifier predicting clean versus noisy data. Due to the imbalance between amounts of clean and noisy utterances, we had to oversample noisy frames to ensure that every mini-batch contained equal number of clean

Table 1: Average word error rates (WER%) on Aurora-4 dataset on all test conditions, including seen and unseen noise and unseen microphone. The first column specifies the number of noise conditions used for the training. The results in the last row are from a preliminary experiment with layer-wise pre-training, close to state-of-the-art model and a corresponding invariance training starting with a pretrained model.

Noise	Inv	BL	A		B		C		D

and noisy speech frames.

Table 1 summarizes the results. Figure 2 visualizes the word error rate (WER) for the baseline multi-condition training and invariance training as the number of seen noise types varies. We conclude that the best performance gain is achieved when a small number of noise types are available during training. It can be seen that invariance training is able to generalize better to unseen noise types compared with multi-condition training.

We note that our experiments did not use layer-wise pre-training, commonly used for small datasets. The baseline WERs reported are very close to the state-of-the-art. Our preliminary experiments on a pre-trained network (better overall WER) when using all noise types (last row of Table 1) for training show the same trend as the non-pretrained networks.

5. Discussion

This paper presents the application of generative adversarial networks and invariance training for noise robust speech recognition. We show that invariance training helps the ASR system to generalize better to unseen noise conditions and improves the word error rate when a small number of noise types are seen during training. Our experiments show that in contrast to the image recognition task, in speech recognition, the domain adaptation network suffers from underfitting. Therefore, the gradient of the L_3 term in Eq. 1 is unreliable and noisy. Future research includes enhancements to the domain adaptation network while exploring alternative network architectures and invariance-promoting loss functions.

6. Acknowledgments

We would like to thank Yaroslav Ganin, David Warde-Farley for insightful discussions, developers of Theano Theano Development Team (2016), Blocks, and Fuel van Merriënboer et al. (2015) for great toolkits.
